EE 720: An Introduction to Number Theory and Cryptography (Spring 2019)

Lecture 5 — January 17, 2019

Instructor: Saravanan Vijayakumaran Scribe: Saravanan Vijayakumaran

1 Lecture Plan

- Exercises to see utility of the perfect adversarial indistinguishability definition.
- Motivate computational security
- Define computationally secure encryption
- Define pseudorandom generators

2 Exercises on perfect adversarial indistinguishability

- We know that the shift cipher is perfectly secret only if the message consists of a single character. Suppose we encrypt a two-character message using the shift cipher. Construct an adversary in the perfect indistinguishability experiment whose probability of success is better than $\frac{1}{2}$.
- We said that the one-time pad is secure only if the key is used exactly once. Consider the case when an n-bit uniformly chosen key is used to encrypt two n-bit messages m_1 and m_2 using the one-time pad, i.e. $c_1 = m_1 \oplus k, c_2 = m_2 \oplus k$. Construct an adversary in the perfect indistinguishability experiment whose probability of success is better than $\frac{1}{2}$.

3 Computational Security

- To avoid the limitations of perfect secrecy, the weaker notion of computational secrecy is used in modern cryptography.
- Concrete guarantees of security are difficult to provide
- In the asymptotic approach, the cryptographic schemes as well as the involved parties are parametrized by an integer-valued security parameter n (typically the key length)
- Computational security allows two relaxations
 - Security is only guaranteed against adversaries with randomized attack algorithms with running time which is polynomial in n.
 - The adversary is allowed to succeed with negligible probability, i.e. the success probability is asymptotically smaller than any inverse polynomial in n.

Definition (Page 48 of KL). A function f from the natural numbers to the non-negative real numbers is **negligible** if for every positive polynomial p there is an N such that for all integers n > N it holds that $f(n) < \frac{1}{p(n)}$.

Examples: 2^{-n} , $2^{-\sqrt{n}}$, $n^{-\log n}$

• Negligible success probabilities obey certain closure properties.

Proposition (Page 49 of KL). Let $negl_1$ and $negl_2$ be negligible functions. Then,

- 1. The function $negl_3$ defined by $negl_3(n) = negl_1(n) + negl_2(n)$ is negligible.
- 2. For any positive polynomial p, the function negl_4 defined by $\operatorname{negl}_4(n) = p(n) \cdot \operatorname{negl}_1(n)$ is negligible.
- The second part of the proposition implies that if a certain event occurs with only negligible probability in a certain experiment, then the event occurs with negligible probability even if the experiment is repeated polynomially many times.
- General framework of any computational security definition: A scheme is secure if for every probabilistic polynomial-time adversary \mathcal{A} carrying out an attack of a formally specified type, the probability that \mathcal{A} succeeds in the attack (where success is also formally specified) is negligible.
- Necessity of the relaxations
 - Exclude brute-force attackers
 - Exclude pure-guess attackers who succeed with exponentially small probability

3.1 Defining Computationally Secure Encryption

- We need to introduce the security parameter n in our syntax of private-key encryption.
- We assume $\mathcal{M} = \{0, 1\}^*$.
- We allow the decryption algorithm to output an error in case it is presented with an invalid ciphertext.

Definition. A private-key encryption scheme is a tuple of probabilistic polynomial-time algorithms (Gen, Enc, Dec) such that:

- 1. The key-generation algorithm takes 1^n as input and gives key k, i.e. $k \leftarrow \text{Gen}(1^n)$.
- 2. For $m \in \{0,1\}^*$, $c \leftarrow Enc_k(m)$.
- 3. For ciphertext c, $Dec_k(c) = m$ or error indicator \perp .

It is required that for every n, c, k, we have $Dec_k(Enc_k(m)) = m$.

3.2 Indistinguishability in the presence of an eavesdropper

- We consider the ciphertext-only attack where the adversary observes a single ciphertext.
- Our definition will resemble the perfect adversarial indistinguishability definition except for two differences:
 - The experiment is parametrized by n
 - We require the adversary to output equal length messages m_0, m_1 . (See exercise 3.2 of KL)
- Consider the following experiment $\mathtt{PrivK}^{\mathtt{eav}}_{\mathcal{A},\Pi}(n)$:
 - 1. The adversary \mathcal{A} is given 1^n and outputs a pair of arbitrary messages $m_0, m_1 \in \mathcal{M}$ with $|m_0| = |m_1|$.
 - 2. A key k is generated using Gen, and a uniform bit $b \in \{0,1\}$ is chosen. Ciphertext $c \leftarrow \operatorname{Enc}_k(m_b)$ is computed and given to A. This ciphertext c is called the *challenge ciphertext*.
 - 3. \mathcal{A} outputs a bit b'.
 - 4. The output of the experiment is defined to be 1 if b' = b, and 0 otherwise. We write $\text{PrivK}_{\mathcal{A},\Pi}^{\text{eav}}(n) = 1$ if the output of the experiment is 1 and in this case we say that \mathcal{A} succeeds.

Definition. A private-key encryption scheme $\Pi = (\textit{Gen}, \textit{Enc}, \textit{Dec})$ has indistinguishable encryptions in the presence of an eavesdropper, or is EAV-secure, if for all probabilistic polynomial-time adversaries A there is a negligible function negl such that, for all n,

$$\Pr\left[\mathit{PrivK}^{\mathit{eav}}_{\mathcal{A},\Pi}(n) = 1\right] \leq \frac{1}{2} + \mathit{negl}(n).$$

4 Pseudorandom Generators

- It is not known how to construct computationally secure encryption schemes without making any assumptions. We need to assume the existence of pseudorandom generators.
- A pseudorandom generator is an efficient (polynomial-time), deterministic algorithm for transforming a short, uniform bitstring called the *seed* into a longer, "uniform-looking" or "pseudorandom" output string.
- Pseudorandomness is a property of a distribution on strings.
- Some desirable properties of a pseudorandom generator:
 - Any bit of the output should be equal to 1 with probability close to $\frac{1}{2}$.
 - The parity of any subset of the output bits should be equal to 1 with probability close to $\frac{1}{2}$.

• A good pseudorandom generator should pass all efficient statistical tests, i.e. for any efficient statistical test or distinguisher D, the probability that D returns 1 given the output of the pseudorandom generator should be close to the probability that D returns 1 when given a uniform string of the same length.

Definition. Let l be a polynomial and let G be a deterministic polynomial-time algorithm such that for any n and $s \in \{0,1\}^n$, the result G(s) is a string of length l(n). We say that G is a **pseudorandom generator** if the following conditions hold:

- 1. **Expansion:** For every n it holds that l(n) > n.
- 2. **Pseudorandomness:** For any PPT algorithm D, there is a negligible function **negl** such that

$$\left|\Pr\left[D\left(G(s)\right)=1\right]-\Pr\left[D(r)=1\right]\right|\leq \operatorname{\textit{negl}}(n),$$

where the first probability is taken over uniform choice of $s \in \{0,1\}^n$ and the randomness of D, and the second probability is taken over uniform choice of $r \in \{0,1\}^{l(n)}$ and the randomness of D.

We call l the **expansion factor** of G.

- Example of a non-pseudorandom generator: Define $G: \{0,1\}^n \to \{0,1\}^{n+1}$ as $G(s) = s \| (\bigoplus_{i=1}^n s_i)$.
- What happens if remove the restriction that *D* is polynomial time?
- There is no known way to prove the unconditional existence of pseudorandom generators. We will some constructions of stream ciphers which we hope are pseudorandom generators.
